Abstract
Rapid maxillary expansion is a commonly used treatment modality for the correction of maxillary transverse deficiency in cleft and non-cleft patients. Additional beneficial effects of rapid maxillary expansion includes improvement in nasal stenosis, abnormal breathing pattern and conductive hearing loss. The improvements in the hearing have been linked to the improved function of the two soft palatal muscles, the tensor veli palatini and the levator veli palatini muscles. This study aims to explore the different studies which have evaluated the effects of rapid maxillary expansion on hearing in cleft and non cleft patients.

Keywords: Rapid maxillary expansion, conductive hearing loss, cleft lip and palate

Introduction
Rapid maxillary expansion (RME) is a therapeutic procedure that results in increase in the transverse dimensions of the maxillary arch. RME causes the posterior teeth and alveolar processes to move buccally¹. According to a systematic review by Liu et al., in 2015 the mid palatal suture opens approximately 12–52.5 percent of the total screw expansion, but the study could not confirm whether the mid palatal sutural opening was parallel or triangular².

According to the Global Burden of Disease study the years lived with disability and hearing loss was found to be the fourth leading cause globally³. Hearing loss is classified into: sensorineural hearing loss and conductive hearing loss (CHL). Sensorineural hearing loss is characterized by lesions in the cochlea or involves the eight cranial nerve⁴. CHL on the other hand is an auditory disorder with elevated air-bone conduction thresholds.

CHL can be classified according to the severity and types of the physical changes imposed on the outer or middle ear. In normal hearing the air and bone conduction thresholds interweave. In mild CHL the air-bone gap is 20–30 dB, in moderate CHL the air-bone gap is 30–45 dB and in severe CHL the air-bone gap is 45-60 dB⁵.

Patients who suffer from maxillary constriction are 3.5 times more likely to suffer from CHL⁶. Children with cleft lip and palate present with a significantly higher prevalence of otitis media with effusion as
compared to non-cleft patients. Aberrant levator veli palatini muscle positioning, as well as an abnormal fusion with the tendon of the tensor veli palatini muscle, predisposes them to otopathologies. Proper hearing system, anatomical and physiological integrity, auditory pathway maturity and sound stimulation are essential for the acquisition and development of verbal language. Maxillary expansion has been shown to improve hearing in patients with CHL. According to a systematic review by Fagundes et al., in 2017 based on nine studies, maxillary expansion results in hearing level improvement by 2-19 dB.

This manuscript aims to describe and provide insights into the effects of maxillary expansion on hearing in cleft and non-cleft patients.

Methods of hearing assessment

Audiometry

Pure tone audiometry is considered as the gold standard test in the objective assessment of hearing levels and pure tone thresholds at different frequencies. Audiometer devices are used to quantitatively measure the air conduction and bone conduction pure tone thresholds. According to the American National Standards Institute Specification for audiometer devices, there are four types of audiometers, with Type 1 having the maximum features and Type 4 having the least features. Type 1 audiometer is a full-featured diagnostic audiometer. Type 1 audiometer device contains earphones, bone vibrators, loudspeakers, masking noise, etc and can be considered as a full-featured diagnostic audiometer. A Type 4 audiometer on the other hand is a simple screening machine with earphones, with no other special features.

The test involves the delivery of sound by an earphone at different frequencies, and the hearing levels are assessed for each ear separately. Bone conduction thresholds are assessed by placing a vibrator on the skull, which results in the stimulation of cochlea directly, without involving the outer and the middle ear. A comparison of the air conduction and bone conduction thresholds provides an estimate of the status of the conductive or sensory hearing loss.

Tympanometry

Tympanometry is an objective test of acoustic admittance of the middle ear as a function of air pressure in a sealed ear canal. The test involves the introduction of varying air pressure in the ear canal, which causes the tympanic and ossicular chain to stiffen. As the air pressure is varied in the ear canal, the admittance flowing into the middle ear is decreased, resulting in more sound pressure remaining in the ear canal. The result is a tympanogram, with a normal tympanogram having a single clearly defined peak at near atmospheric pressure, which is represented as Type A. Type B tympanogram has an abnormally low admittance with no discernible peak. Type C tympanogram has normal admittance, with a peak occurring at negative pressure.

**Discussion**

Several studies have evaluated the effects of RME on hearing loss, with the first attempt by Laptook, who observed an improvement in hearing in a patient after 1.5 weeks of expansion. The hearing level improvement was retained till 1.5 years of treatment. Timms, and Taspinar et al., observed considerable hearing improvement after RME. Ceylan et al., found that hearing levels were significantly improved during the active expansion period, but there was a relapse during the retention period. In a recent and long-term study, Kilic et al., carried out RME and observed the hearing level changes for a period of two years. There was an improvement in the hearing levels after RME and the improvement was stable after two years. According to a systematic review by Fagundes et al., the authors stressed that more controlled and randomized studies were necessary to investigate this issue further. In a recent study by...
Singh et al., which evaluated the effects of RME on hearing and speech production in bilateral cleft lip and palate patients, there was a significant improvement in the hearing levels in children with normal hearing and mild conductive hearing loss. In a study by Fatima et al., which evaluated the effects of RME on hearing in unilateral cleft lip and palate patients, there were no improvements in the hearing levels and middle ear volume after RME and six months retention period.

Physiologically, the levator veli palatini and the tensor veli palatini opens and closes the orifice of the eustachian tube resulting in humidification and lubrication of the inner ear. If the palatal arches are high and the maxillary arch is constricted, these muscles insert in a stretched, hypo functional, and cramped state resulting in obstruction in the mucus deflection. The mass of mucus and the virulent exudates leads to recurrent serous otitis media.

Active opening of eustachian tube is mainly accomplished by the medial portion of tensor veli and levator veli palatini muscles. RME brings the muscular ends near the tubal ostia which may result in an improvement in the opening and closing of the eustachian tube. Rapid separation of the palate may stretch the tensor veli and the levator veli palatini muscles resulting in the equalisation of air pressure on either side of the tympanic membrane.

Secondly, RME widens the nasal airway dimensions, which results in natural physiologic function and reduction in upper respiratory infections, nasal allergies, respiratory morbidity, and otitis media, which are the most common causes of hearing loss.

Among the cleft lip and palate patients hearing levels have been shown to improve in bilateral cleft lip and palate patients, while in another study contradictory results were produced in unilateral cleft lip and palate patients. This could be due to the abnormal eustachian tube opening mechanism in the cleft palate patients. The tubal lumen of the eustachian tube is less C-shaped in cleft palate patients and the insertion angle of the tensor veli palatini muscle into the cartilage has been found to be narrower than in normal patients, which results in less efficient pull force leading to eustachian tube dysfunctions.

In conclusion, maxillary expansion may result in hearing improvement in growing children and adolescents. Although, more studies with longer follow ups and control groups are needed to reach a more conclusive evidence.
